Carotid Artery Stenosis: Gray-Scale and Doppler US Diagnosis—Society of Radiologists in Ultrasound Consensus Conference

The Society of Radiologists in Ultrasound convened a multidisciplinary panel of experts in the field of vascular ultrasonography (US) to come to a consensus regarding Doppler US for assistance in the diagnosis of carotid artery stenosis. The panel’s consensus statement is believed to represent a reasonable position on the basis of analysis of available literature and panelists’ experience. Key elements of the statement include the following: (a) All internal carotid artery (ICA) examinations should be performed with gray-scale, color Doppler, and spectral Doppler US. (b) The degree of stenosis determined at gray-scale and Doppler US should be stratified into the categories of normal (no stenosis), <50% stenosis, 50%–69% stenosis, ≥70% stenosis to near occlusion, near occlusion, and total occlusion. (c) ICA peak systolic velocity (PSV) and presence of plaque on gray-scale and/or color Doppler images are primarily used in diagnosis and grading of ICA stenosis; two additional parameters, ICA-to–common carotid artery PSV ratio and ICA end-diastolic velocity may also be used when clinical or technical factors raise concern that ICA PSV may not be representative of the extent of disease. (d) ICA should be diagnosed as (i) normal when ICA PSV is less than 125 cm/sec and no plaque or intimal thickening is visible; (ii) <50% stenosis when ICA PSV is less than 125 cm/sec and plaque or intimal thickening is visible; (iii) 50%–69% stenosis when ICA PSV is 125–230 cm/sec and plaque is visible; (iv) ≥70% stenosis to near occlusion when ICA PSV is greater than 230 cm/sec and visible plaque and lumen narrowing are seen; (v) near occlusion when there is a markedly narrowed lumen at color Doppler US; and (vi) total occlusion when there is no detectable patent lumen at gray-scale US and no flow at spectral, power, and color Doppler US. (e) The final report should discuss velocity measurements and gray-scale and color Doppler findings. Study limitations should be noted when they exist. The conclusion should state an estimated degree of ICA stenosis as reflected in the above categories. The panel also considered various technical aspects of carotid US and methods for quality assessment and identified several important unanswered questions meriting future research.

A panel of experts from a variety of medical specialties was convened under the auspices of the Society of Radiologists in Ultrasound to arrive at a consensus about the performance of Doppler ultrasonography (US) to aid in diagnosis of internal carotid artery (ICA) stenosis. The panel met in San Francisco, Calif, October 22–23, 2002, and drew up a consensus statement. Although there are several facets of carotid disease that could be considered by such a panel, carotid stenosis (and by extension, carotid occlusion) is by far the most common pathologic process involving carotid arteries. Furthermore, the clinical suspicion of ICA stenosis is responsible for most of the referrals for carotid imaging. Authors of recent major studies have shown a decrease in stroke risk when carotid endarterectomy is performed for carotid stenosis (1–4). The performance of carotid US and the interpretation of US results vary considerably.
BACKGROUND AND SUMMARY OF THE CONFERENCE PARTICIPANTS

METHODS AND CONFERENCE PREPARATIONS

Conference Participants

Prior to the meeting, 30 representative articles were selected by the moderator (E.G.G.) and sent to conference participants, along with a summary spreadsheet with such information as the purpose of the research, the statistical methods used, and the pertinent results and conclusions (Tables 1, 2) (6–26). The panel consisted of a moderator and 16 panelists from various medical specialties.

Background and Summary of the Literature

Historically, clinical studies of carotid artery disease have classified patients in two groups: symptomatic and asymptomatic. The former group of patients typically has had a neurologic event (stroke, transient ischemic attack, or amaurosis fugax) secondary to cerebral ischemia, likely as a result of an embolic event arising from atherosclerotic disease at the carotid bifurcation. Patients in this group have formed the basis for such well-known studies as the North American Symptomatic Carotid Endarterectomy Trial (1) and the European Symptomatic Carotid Endarterectomy Trial (3).

The asymptomatic group includes patients who have not had a neurologic event. The seminal investigation in this population, the Asymptomatic Carotid Artery Study (2), included patients who, though they had not had a neurologic event, typically had clinical markers for diffuse atherosclerosis. Overall, the prevalence of significant (>50%) stenotic disease in symptomatic patients is stated as being in the range of 18%–20% (27,28), while the prevalence in asymptomatic patients referred for carotid imaging is 14% (29). The prevalence of ICA disease in the asymptomatic group, therefore, approaches that found in symptomatic patients.

Doppler US is by far the most common imaging examination performed worldwide to aid in the diagnosis of carotid disease. Given the prevalence of patients with carotid disease and the frequency with which patients are referred for carotid imaging, the number of carotid US examinations performed annually is considerable (22). This imaging modality is increasingly becoming the only examination performed before surgical intervention. It was estimated by the panels that as many as 80% of patients in the United States undergo carotid endarterectomy after a US examination as the only preoperative imaging study. Therefore, it is of utmost importance that information provided by the US examination be reproducible and reliable.

Considerable gains have been made in the quality of US examinations of the carotid arteries over the past 2 decades. The technology has experienced great advances in equipment, ranging from continued improvements in gray-scale resolution to landmark advances in Doppler methods, including color Doppler imaging. The imaging community has gained expertise in performance of carotid US and interpretation of the results through widespread use of technology, research, and continuing medical education. In addition, various accrediting bodies have been established by groups such as the Intersocietal Commission for Accreditation of Vascular Laboratories, the American Institute of Ultrasound in Medicine, and the American College of Radiology in an attempt to improve and standardize the quality of vascular US examinations.

Despite improvements and advances,
the consensus panel agreed that, overall, carotid US is often performed inconsistently within a given laboratory, and there is nonuniformity in practice from one laboratory to the next. In many settings, interpretive criteria for carotid stenosis are either indiscriminately applied or the interpreters are uncertain about exactly how to make the diagnosis of carotid stenosis.

**CONSENSUS CONFERENCE**

The results of the consensus conference regarding performance of carotid US and interpretation of the results and the diagnosis of ICA stenosis can be summarized into six key areas: *(a)* technical considerations, *(b)* diagnostic strata, *(c)* imaging and Doppler parameters, *(d)* Doppler diagnostic thresholds; *(e)* the final report of the gray-scale and Doppler US examinations, and *(f)* quality assessment. The panel identified a number of issues related to performance of carotid US and interpretation of the results and made recommendations to address these issues.

**Technical Considerations**

**Standardization**

**Issue.**—The performance of carotid US examinations is not standardized from laboratory to laboratory. Even within a given laboratory, there is often a failure to follow a consistent protocol.

**Recommendation.**—Examinations of the ICA should be performed with gray-scale, color Doppler, and spectral Doppler US in a standardized fashion, according to a rigidly applied laboratory protocol, in accordance with the standards of one of the accrediting bodies. The panel encourages all sonographers performing carotid US to become credentialed as vascular technologists.

**Positioning and Angulation**

**Issue.**—Errors in positioning the Doppler gate and in accounting for the Doppler angle are common in current clinical practices. Since interpretative criteria for carotid stenosis are heavily based on Doppler velocities, errors in Doppler position and angle correction will lead to serious errors in diagnosis.

**Recommendation.**—The Doppler waveform should be obtained with an angle of insonation less than or equal to 60°, as measurements obtained with an angle of insonation greater than 60° are likely to be inaccurate, even with appropriate angle adjustment, because of the physical properties of Doppler.

**Conflicting opinions.**—Some believed that maintaining a constant angle of insonation of exactly 60° would provide greater consistency. Other panelists did not agree that a fixed angle of insonation for all carotid US examinations is required and instead expressed that it is necessary only to maintain an angle of less than or equal to 60°. It was thought that further investigation on this matter is warranted.

**Sample Volume Position**

**Issue.**—Other common technical shortcomings in ICA examinations include incorrect positioning of the sample volume, incomplete sampling through an area of stenosis, and failure to depict the distal end of a carotid plaque.

**Recommendation.**—Care should be taken to position the sample volume within the area of greatest stenosis. The ICA must be sampled through the region of stenosis completely until the distal end of the plaque is visualized, to ensure that the site of highest velocity has been located.

**Patient Considerations**

**Issue.**—Several errors may result from problems inherent to the patient, such as extensive plaque calcification, severe ICA tortuosity, and tandem lesions.

**Recommendation.**—It is important to recognize these patient conditions and understand that, in such cases, the examination may be limited.

*NA = not applicable.† Ratio is ICA PSV to distal CCA PSV.‡ NASCET = North American Symptomatic Carotid Endarterectomy Trial.
Equipment

Issue.—There is substantial variability in equipment from machine to machine, from manufacturer to manufacturer, and between older and newer equipment (30–33). This variability in equipment may explain, in part, the lack of agreement and inconsistency in the literature concerning Doppler thresholds for the diagnosis of carotid stenosis.

Recommendation.—The panel encourages US equipment manufacturers to minimize equipment variability by establishing industry-wide standards for Doppler measurement and calibration and the development of a reliable Doppler phantom that can be made readily available to industry and to vascular laboratories.

Diagnostic Strata
Methods of Reporting

Issue.—Methods by which the degree of ICA stenosis is reported vary from laboratory to laboratory, as well as within some laboratories. Some report an estimate of the specific percentage of stenosis, others stratify their estimates into five or six diagnostic categories or gradations of stenosis.

Recommendation.—Doppler US cannot be used to predict a single percentage of stenosis. Therefore, the consensus panelists strongly recommend the use of defined diagnostic strata. Laboratories should establish protocols for stratifying the degree of ICA stenosis, and, once established, these criteria should be consistently applied.

Doppler Measurement Variability

Although investigators have confirmed that the average Doppler velocity rises in direct proportion to the degree of stenosis as determined with angiography (18,26), there are very wide ranges of Doppler values around those means, which makes it impossible to classify lesions into gradations as narrow as 10% (Figure) (18,34). Even in evaluations of the ability of Doppler US to help estimate the degree of ICA stenosis, and, once established, these criteria should be consistently applied.

Stenosis of Less than 50%

Issue.—In many laboratories, stratification or diagnosis of minor (<50%) degrees of ICA stenosis is based on Doppler findings.

Recommendation.—Because Doppler is inaccurate for subcategorizing stenoses less than 50%, these stenoses should be reported under a single category as “<50% stenosis.” Subcategories for minor degrees of stenosis should not be used.

Stratification of Stenoses

Issue.—How should reporting of ICA stenosis be stratified?

Recommendation.—The consensus panel recommends stratification of the degree of stenosis on the basis of gray-scale and Doppler US results into the following strata: normal (no stenosis), <50% stenosis, 50%–69% stenosis, ≥70% stenosis but less than near occlusion, near occlusion, and total occlusion.

Discussion.—The threshold of 70% stenosis was chosen because it was believed to be the threshold currently used by most major vascular centers for surgical intervention. The panel agreed, however, that in some laboratories, there may be a compelling reason to choose a different stratification scheme. The diagnoses of near occlusion and total occlusion are usually not based primarily on the Doppler measurement of velocity but rather on gray-scale and color and/or power Doppler imaging.

Imaging and Doppler Parameters
Key Components of ICA Examination

Issue.—What are the key components of the US examination of the ICA?

Recommendation.—The ICA US examination should consist of gray-scale imaging, color Doppler imaging, and spectral Doppler velocity determination. Because stenosis is typically an area of narrowing caused by plaque, with a focal area of increased velocity and a poststenotic disturbed flow, the location and characteristics of plaque in the ICA should be determined. The color Doppler appearance of the lumen should also be assessed.

Primary US Parameters

Issue.—Numerous imaging and Doppler parameters are currently used at various laboratories for the evaluation of ICA stenosis, including ICA PSV, ICA EDV and ICA/CCA PSV ratio, CCA EDV, and ICA/CCA EDV ratio. The application of these parameters for diagnosis of ICA stenosis varies from laboratory to laboratory and sometimes within a given laboratory.

Recommendation.—The panel suggested that the ICA PSV and the presence of plaque on gray-scale and/or color Doppler US images are the parameters that should be used when diagnosing and grading ICA stenosis.

Discussion.—The ICA PSV is easy to obtain and has good reproducibility and should be used in conjunction with available gray-scale and color Doppler information to ensure concordance of diagnostic information. The degree of stenosis estimated by using ICA PSV and the degree of narrowing of the ICA lumen on gray-scale and color Doppler images should be similar.
Additional US Parameters

**Issue.**—Should other Doppler parameters be used and, if so, when?

**Recommendation.**—Two additional parameters, ICA/CCA PSV ratio and ICA EDV, are useful for internal checks or may be used when ICA PSV may not be representative of the extent of disease owing to technical or clinical factors such as in the presence of tandem lesions, contralateral high-grade stenosis, discrepancy between visual assessment of plaque and ICA PSV, elevated CCA velocity, hyperdynamic cardiac state, or low cardiac output. For example, in a patient with low cardiac output, the ICA PSV may be disproportionately low when compared with the ICA/CCA PSV ratio. This discrepancy should prompt the interpreter to consider all gray-scale and Doppler information when stratifying the degree of ICA stenosis. In particular in such cases, the interpretation should be based more heavily on the ICA/CCA PSV ratio than on absolute values such as the ICA PSV or ICA EDV. The panel believed that outlining the reasons for making diagnostic choices that are not in keeping with usual practice should be included in the final report.

Doppler Diagnostic Thresholds

**Issue.**—Published literature is replete with velocity thresholds for categorizing ICA stenosis (Table 1). Tremendous variation exists among these studies in the methods used to assess individual Doppler parameters and in the thresholds recommended for diagnosing ICA stenosis (7).

**Recommendation.**—The consensus panel developed recommendations for diagnosis and stratification of ICA stenosis (Table 3). These recommendations were derived from analysis of numerous studies and do not represent the results of any one laboratory or study. For a particular laboratory setting, internal validation is encouraged when possible. This may yield alternative diagnostic criteria that can be used successfully at that facility. However, each laboratory should have a single set of diagnostic criteria that is applied uniformly. The following points are included in Table 3 and should be considered in the diagnosis of ICA stenosis:

1. The ICA is considered normal when ICA PSV is less than 125 cm/sec and no plaque or intimal thickening is visible sonographically. The ICA/CCA PSV ratio < 2.0 and ICA EDV < 40 cm/sec.

2. A ≤50% ICA stenosis is diagnosed when ICA PSV is less than 125 cm/sec and plaque or intimal thickening is visible sonographically. The ICA/CCA PSV ratio < 2.0 and ICA EDV < 40 cm/sec.

3. A 50%–69% ICA stenosis is diagnosed when ICA PSV is 125–230 cm/sec and plaque is visible sonographically. Additional criteria include ICA/CCA PSV ratio > 2.0 and ICA EDV of 40–100 cm/sec.

4. A ≥70% ICA stenosis but less than near occlusion of the ICA is diagnosed when the ICA PSV is greater than 230 cm/sec and visible plaque and luminal narrowing are seen at gray-scale and color Doppler US. Additional criteria include ICA/CCA PSV ratio > 4 and ICA EDV > 100 cm/sec. The higher the Doppler parameter lies above the threshold of 230 cm/sec, the greater the likelihood of severe disease.

5. In cases of near occlusion of the ICA, the velocity parameters may not apply, since velocities may be high, low, or undetectable. This diagnosis is established primarily by demonstrating a markedly narrowed lumen at color or power Doppler US (35).

6. Total occlusion of the ICA should be suspected when there is no detectable patent lumen at gray-scale US and no flow with spectral, power, and color Doppler US. Magnetic resonance (MR) angiography, computed tomographic (CT) angiography, or conventional angiography may be used for confirmation in this setting (35).

Final Report of the Gray-Scale and Doppler US Examination

**Issue.**—The structure and content of final reports of carotid US examinations vary greatly from laboratory to laboratory, as well as within given laboratories.

**Recommendation.**—The final report of the gray-scale and Doppler US interpretation of the ICA examination should include the following:

- **Body of the report.**—(a) Pertinent US findings, including velocity measurements and gray-scale findings (presence, location, and characteristics of ICA plaque), as well as color Doppler findings when appropriate; (b) comments about limitations of the study or deviations from usual interpretive criteria due to technical factors or hemodynamic considerations; and (c) comparison with results of prior studies.

- **Conclusion or impression.**—Estimated degree of ICA stenosis, categorized by the laboratory’s established diagnostic criteria (modified, as appropriate, by technical factors or hemodynamic considerations).

Quality Assessment

**Need for Quality Assessment**

**Issue.**—Should every laboratory have a system for quality assessment?

**Recommendation.**—All laboratories should institute a program of quality assessment.

### Internal Validation of Doppler Thresholds

**Issue.**—Development of internally validated Doppler thresholds may be difficult given the infrequency of correlative angiograms at most institutions.

**Recommendation.**—The panel agreed that it may not always be feasible to obtain angiographic or clinical correlation for quality assessment of US studies at
each laboratory. For this reason, the consensus panel developed the table of recommended Doppler thresholds for diagnosis of ICA stenosis (Table 3), which can be applied at laboratories that cannot validate their own Doppler thresholds on the basis of correlative imaging or clinical information.

**Discussion:** Although angiography has historically been considered the “gold standard” for assessing Doppler thresholds for various degrees of ICA stenosis, few angiographic examinations are still performed. Those that are performed at a given institution are probably not representative cases, but rather those cases in which the US results were equivocal or otherwise problematic. The use of CT angiography and MR angiography for correlation has not, as yet, been fully validated (36).

**Reference Standard**

**Issue.**—When angiography is used as the reference standard for assessment of Doppler criteria for ICA stenosis, different techniques for measuring ICA stenosis have been used.

**Recommendation.**—The panel recommended that the NASCET method of carotid stenosis measurement should be employed when angiography is used to correlate the US findings.

**Discussion.**—In this method, the narrowest portion of the vascular lumen was compared with the “normalized lumen distally” (37). In the European Symptomatic Carotid Trial study and studies performed prior to the NASCET study, the degree of stenosis was determined by comparing the narrowest diameter of the residual lumen to an estimate of the original lumen in the same area. Because the original lumen cannot be depicted on the angiogram, exact measurement is impossible. While the NASCET method of measurement may not reflect the burden of atherosclerosis in the proximal ICA, it does minimize the amount of interobserver variability.

**OTHER CONSIDERATIONS**

**Patient Surveillance**

The panel discussed the issue of appropriate follow-up of asymptomatic patients with known ICA stenosis, as well as of patients at high risk for ICA stenosis or stroke. The panelists agreed that patients with a ≥50% stenosis of the ICA who do not undergo carotid endarterectomy and who may be candidates for prophylactic carotid endarterectomy should be followed up at 6–12-month intervals, and high-risk patients with visible plaque and <50% stenosis should be evaluated every 1–2 years. Patients who have normal carotid US studies but marked risk factors might be evaluated every 3–5 years. In all cases of follow-up or surveillance, a complete examination should be performed. Follow-up studies should be compared with results from prior examinations.

**Research Topics**

The panel identified several important unanswered questions that merit future research.

1. What is the role of ICA plaque characterization in carotid disease?
2. What is the role of the ICA intimal-medial thickness? There are several ongoing large clinical trials in which the intimal-medial thickness is being evaluated as a marker of atherosclerotic disease, but there are not yet enough data to establish the role of this measurement in the assessment of carotid disease in individual patients.
3. At follow-up examination, how much of a change in estimated ICA stenosis or ICA PSV should be considered relevant?
4. What criteria should be used to assess patients after ICA surgery or stent placement?
5. Should US be used to screen for carotid disease?
6. Other issues that need to be addressed include the following:
   1. There is considerable variation in Doppler measurements from machine to machine and manufacturer to manufacturer. This should be rectified, because such variation leads to inconsistencies and inaccuracies in diagnosing ICA stenosis.
   2. Phantoms for Doppler US need to be developed to facilitate calibration of Doppler US equipment.
   3. Improved methods for calculating velocity with angle correction should be developed to eliminate or minimize the inconsistency in velocity measurements as the Doppler angle of insonation is changed.
   4. Reliable quality assessment methods should be developed so that laboratories can assess their performance of the carotid US examination. This should lead to greater consistency in the performance of carotid US within each laboratory, as well as from laboratory to laboratory.
